
Ashley G. Boyle, DVM, DACVIM; K. Gary Magdesian, DVM, DACVIM, DACVECC, DACVP; Rebecca E. Ruby, BS

Objective—To assess data regarding clinical features, clinicopathologic and blood gas variables, and outcome from horse and mule foals with confirmed neonatal isoerythrolysis (NI).

Design—Retrospective case series.

Animals—17 horse and 1 mule foals.

Procedure—Medical records of foals (<14 days old) with NI were reviewed. Information collected included signalment; clinical examination findings; results of hematologic, serum and plasma biochemical, and venous blood gas analyses and urinalysis; treatments; and outcome.

Results—Data from 17 horse foals and 1 mule foal with NI (mean age, 71 hours) were evaluated. Many foals had high serum indirect and direct bilirubin concentrations and sorbitol dehydrogenase activity. Whole blood immunoglobulin concentrations were >400 mg/dL in 4 of 15 foals. Fresh whole blood transfusions were administered to 10 of 18 foals. Among the blood factors implicated in 11 foals, one (Dg) had not previously been associated with NI. Of 10 foals that received blood transfusions, 7 had significant improvements in Hct and hemoglobin concentration and RBC count. Additional information collected included details of administration of blood products and corticosteroid treatment; heart rate, respiratory rate, and rectal temperature before and after the first blood or plasma transfusion; hemoglobin concentration, Hct, RBC count, icterus index (ie, the value that indicates the relative amount of bilirubin in serum or plasma by assessment of the intensity of color of the sample), and plasma protein and fibrinogen concentrations before and after the first blood or plasma transfusion; serum anion gap; serum immunoglobulin immunoassays; adequate passive transfer of immunoglobulin was determined by use of 1 of 2 semiquantitative commercial immunoglobulin immunoassays; adequate passive transfer was defined as whole blood immunoglobulin concentration >800 mg/dL. The reference ranges for all these variables in neonatal horses were not created specifically; published reference ranges were used.

Conclusions and Clinical Relevance—Data suggest that blood factor Dg may be associated with NI in foals. Liver disease may be concurrent with NI in foals, and NI can develop in foals with inadequate passive transfer of colostral antibodies. Whole blood transfusions were successful at increasing oxygen-carrying capacity and improving peripheral tissue oxygenation in NI-affected foals. With appropriate treatment, the prognosis for foals with NI is good.

From the Veterinary Medical Teaching Hospital (Boyle, Ruby) and the Department of Medicine and Epidemiology (Magdesian), School of Veterinary Medicine, University of California, Davis, CA 95616. Dr. Boyle’s present address is Section of Field Service, New Bolton Center, School of Veterinary Medicine, University of Pennsylvania, Kennett Square, PA 19348.

Presented in part at the 23rd Annual Meeting of the American College of Veterinary Internal Medicine, Baltimore, June 2005. Address correspondence to Dr. Boyle.

1276 Scientific Reports: Retrospective Study
creatinine, direct bilirubin, indirect bilirubin, total bilirubin, BUN, total CO2, and total protein concentrations before and after the first blood or plasma transfusion; and venous blood pH, venous base excess, venous bicarbonate concentration, and central venous oxygen tension (Pcvo2) before and after the first blood or plasma transfusion. Posttransfusion data were collected within 4 hours of and 24 hours after the first blood or plasma transfusion for heart rate, respiratory rate, rectal temperature, and venous blood gas values; 0.5 to 4 days after the first blood or plasma transfusion for hematologic variables; and 0.5 to 5 days after the first blood or plasma transfusion for serum, plasma, and urine biochemical variables.

The NI-associated blood factor antigens on a foal’s RBCs were indirectly determined via identification of the blood factor alloantibodies in the dam. Three dilutions of the mare’s serum or colostrum were evaluated for anti-erythrocyte hemolysin and agglutinin activities against a panel of washed RBCs from 11 horses and 1 donkey of known blood types (performed at the Veterinary Genetics Laboratory, School of Veterinary Medicine, University of California, Davis, as previously described). From the recorded data, blood volume administered per kilogram was calculated for foals with known body weights and estimated for foals with unknown body weights (body weight assumed to be 50 kg [110 lb] on the basis of breed). Hospital visit data were computer generated for all foals 0 to 14 days of age that were treated at the VMTH from 1988 to 2003. Survival-to-discharge status was determined for hospitalized cases as well as the field service cases for which follow-up history (minimum duration, 3 weeks) was available. Long-term outcome data were obtained from medical records and via telephone conversations with owners and farm managers. Long-term outcome was considered successful if the horse was alive ≥ 1 year after discharge.

Statistical analyses—A nonparametric Mann–Whitney test was used to compare Hct values at initial evaluation between foals that had Hct ≥ 11% initially and foals that had Hct < 11% initially. A nonparametric Wilcoxon matched-pairs signed rank test was performed to evaluate differences between values before and after the first blood transfusion for the following variables: heart rate; respiratory rate; rectal temperature; hemoglobin concentration; Hct; RBC count; icterus index; plasma protein concentration; plasma fibrinogen concentration; venous blood pH; venous base excess; venous bicarbonate concentration; Pcvo2; anion gap; and serum creatinine, direct bilirubin, indirect bilirubin, total bilirubin, BUN, total CO2, and total protein concentrations. The nonparametric Wilcoxon matched-pairs signed rank test was used to evaluate differences between values before and after the first plasma transfusion for the following variables: heart rate; respiratory rate; rectal temperature; hemoglobin concentration; Hct; RBC count; icterus index; plasma protein concentration; venous blood pH; venous base excess; venous bicarbonate concentration; Pcvo2; anion gap; and serum direct bilirubin, indirect bilirubin, total bilirubin, BUN, creatinine, total CO2, and total protein concentrations. Also, data regarding clinical variables after transfusion of plasma or blood were combined for analysis. In statistical comparisons, a value of P < 0.05 was considered significant.

Results

Signalment—Eighteen foals fulfilled the criteria for inclusion in the study. An additional foal that was dead on arrival at the VMTH was suspected to have NI but was not included in the study because the selection criteria could not be met. Among the 18 foals, there was 1 mule, 2 American Paints, 1 warmblood cross, 1 Standardbred, 8 Thoroughbreds, and 5 Quarter Horses; the percentage of foals with NI by breed was 5.5%, 11%, 5.5%, 5.5%, 44.4%, and 27.8%, respectively. Among the general population of neonatal equids evaluated at the VMTH during the study period, the percentages of foals of these breeds were 1.1%, 3.6%, 5.8%, 3.2%, 31%, and 20.3%, respectively. In the study group, mules, American Paints, Standardbreds, and Thoroughbreds were overrepresented. There were no Arabsians, American Miniature Horses, or draft breeds with NI despite these breeds representing 10.8%, 4.2%, and 2% of the general neonatal equid population at the VMTH. The 18 foals with NI represented 1% of the total population of equids (n = 1988) aged 0 to 14 days evaluated at the VMTH during the study period. There were 12 females among the 18 foals with NI; among the total VMTH population of 1988 neonatal equids, there were 913 (45.9%) females and 994 (50%) males (sex was not recorded for 81 [4.1%] foals). Mean age at initial evaluation was 71 hours (age range, 7.5 to 288 hours; median age, 60 hours).

Clinical examination findings—Clinical examination findings were available for 17 of the 18 foals. Each foal’s attitude at initial evaluation was classified. Of the 17 foals, 10 were quiet, alert, and responsive; 4 were weak; and 3 were obtunded. Initial rectal temperature ranged from 35.5° to 39.3°C (96°F to 102.8°F); mean, 38.1° ± 1.1°C [100.6° ± 2.0°F]; median, 38.4°C [101.2°F]). Five of the 17 foals were considered febrile (rectal temperature > 38.8°C [101.8°F]). Respiratory rate ranged from 20 to 140 breaths/min (mean, 46 ± 31 breaths/min; median, 40 breaths/min). Six foals were considered tachypneic (respiratory rate > 40 breaths/min). Heart rate ranged from 75 to 144 beats/min (mean, 108 ± 19 beats/min; median, 108 beats/min). Four foals were considered tachycardic (heart rate > 120 beats/min). Additional clinical abnormalities detected in the 17 foals at initial evaluation included icterus (n = 11), cardiac murmurs (4), enlarged umbilicus (1), petechiae (2 [1 of which was the mule foal]), ecchymoses (1 [the mule foal]), hematochezia (1 [the mule foal]), diarrhea (1), contracted tendons (1), seizures (1), and red urine (3 of the 5 foals that urinated during the initial evaluation).

Hematologic findings—Results of a CBC performed at the initial evaluation were available for 16 foals. Hematocrit ranged from 9% to 38.4% (mean,
17.7 ± 9.6%; median, 13.7%; reference range, 33.4% to 46.6%). At the initial evaluation of these 16 foals, 6 had Hct ≤ 11% and 9 had Hct ≤ 15%. Although the Hct was lower in foals that were eventually euthanized, there was no significant difference in initial Hct between the 3 foals that were euthanized (mean, 12.1 ± 2.4%; median, 11%) and the 13 foals that survived (mean, 19 ± 10.2%; median, 16%). At the initial evaluation, hemoglobin concentration ranged from 3.4 to 13.4 g/dL (mean, 6.4 ± 3.0 g/dL; median, 5.3 ± 2.7 g/dL; reference range, 12.2 to 16.6 g/dL) and RBC count ranged from 1.4 to 10.3 X 10^6 cells/µL (mean, 4.3 ± 2.7 X 10^6 cells/µL; median, 3.5 X 10^6 cells/µL; reference range, 8.5 to 12.5 X 10^6 cells/µL). Initial WBC count ranged from 3,200 to 23,400 cells/µL (mean, 11,133 ± 5,963 cells/µL; median, 9,600 cells/µL; reference range, 3,492 to 13,772 cells/µL), and band neutrophil count ranged from 0 to 2,340 bands/µL (mean, 561 ± 839 bands/µL; median, 16 bands/µL; reference range, < 50 bands/µL). Lactate index ranged from 15 to 100 units (mean, 78 ± 27 units; median, 88 units; reference range, 10 to 70 units). Platelet counts ranged from 1,100 to 278,000 platelets/µL (mean, 145,174 ± 80,078 platelets/µL; median, 142,000 platelets/µL; reference range, 100,000 to 225,000 platelets/µL). Plasma fibrinogen concentrations were available for 15 of 19 foals; these values ranged from 300 to 900 mg/dL (mean, 387 ± 192 mg/dL; median, 300 mg/dL; reference range, 95 to 391 mg/dL). Serum total protein concentrations were available for 12 of 19 foals; these values ranged from 3.9 to 7.1 g/dL (mean, 5.5 ± 1.0 g/dL; median, 5.6 g/dL; reference range, 4.5 to 7.7 g/dL).

**Whole blood**—Results of serum and plasma biochemical analyses were available for 14 to 16 foals, depending on the variable. Blood glucose concentration at initial evaluation ranged from 40 to 388 mg/dL (mean, 158 ± 94 mg/dL; median, 139 mg/dL; reference range, 90 to 210 mg/dL). Of 14 foals, 3 were considered to be hyperglycemic and 5 were considered to be hypoglycemic. Six of the 14 foals had a high anion gap; anion gap values ranged from 4 to 30 (mean, 19 ± 9; median, 17; reference range, 11 to 19). In 14 foals, serum creatinine concentration at initial evaluation ranged from 0.8 to 3.4 mg/dL (mean, 1.6 ± 0.9 mg/dL; median, 1.3 mg/dL; reference range, 0.7 to 1.9 mg/dL); 3 foals had mildly high serum creatinine concentrations. Seven of 14 foals had high serum BUN concentrations; concentrations ranged from 8 to 103 mg/dL (mean, 26 ± 24 mg/dL; median, 18 mg/dL; reference range, 10.3 to 27.5 mg/dL). Fifteen of the 16 foals for which serum total bilirubin concentration data were available had high values; concentrations ranged from 2.6 to 32.1 mg/dL (mean, 14.1 ± 9.2 mg/dL; median, 11.6 mg/dL; reference range, 1 to 3 mg/dL). Of the 14 foals for which serum total bilirubin had been fractionated into components, 13 had high serum indirect bilirubin concentrations; concentrations ranged from 2.4 to 23.3 mg/dL (mean, 11.43 ± 5.88 mg/dL; median, 11.3 mg/dL; reference range, 0.6 to 2.6 mg/dL). Five of these 14 foals had high serum direct bilirubin concentrations; values ranged from 0.02 to 18 mg/dL (mean, 2.85 ± 5.24 mg/dL; median, 0.35 mg/dL; reference range, 0.3 to 0.7 mg/dL). Of the 15 foals for which initial serum aspartate aminotransferase activity was known, values ranged from 139 to 1,050 U/L (mean, 331 ± 293 U/L; median, 189 U/L; reference range, 105 to 345 U/L). At initial evaluation, serum alkaline phosphatase activities of 13 foals ranged from 244 to 9,379 U/L (mean, 1,468 ± 1,099 U/L; median, 1,194 U/L; reference range, 0 to 1,497 U/L). Initial serum γ-glutamyl transferase activities of 15 foals ranged from 7 to 67 U/L (mean, 29 ± 16 U/L; median, 32 U/L; reference range, 0 to 104 U/L). Serum SDH activities were known for 16 foals; values ranged from 2 to 486 U/L (mean, 59 ± 135 U/L; median, 10 U/L; reference range, 0.2 to 3.8 U/L). Three, 6, and 14 foals were considered to have high serum aspartate aminotransferase, alkaline phosphatase, and SDH activities, respectively.

A significant (P = 0.02) difference in serum SDH activity between the 6 foals with initial Hct ≤ 11% (mean serum SDH activity, 143.7 ± 202.2 U/L; median, 29.5 U/L) and the remaining 10 foals with initial Hct > 11% (mean serum SDH activity, 8.5 ± 6.5 U/L; median, 5.5 U/L) was detected. Two of the 6 foals with Hct ≤ 11% had liver biopsies performed. Histologic examinations of the liver tissue specimens revealed hepatic necrosis and multifocal, neutrophilic hepatitis with lobular collapse, bile duct hyperplasia, and early fibroplasia in 1 foal and severe, diffuse hemosiderosis with multifocal hepatocellular necrosis, bile duct hyperplasia, and Kupffer cell hyperplasia consistent with massive hemolysis with uptake of iron by the liver in the other foal.

**Urinalysis findings**—Urinalysis data were available for 4 foals. Bilirubinuria was identified in 2 foals. Hemoglobinuria was identified in all 4 foals.

**Assessment of passive transfer**—Whole blood immunoglobulin concentration was assessed in 15 foals; passive transfer was determined to be adequate in 10 of those 15 foals. Among the remaining 5 foals for which data were available, serum immunoglobulin concentration was 400 to 800 mg/dL (n = 1), < 400 mg/dL (3), or < 200 mg/dL (1).

**Venous blood gas analysis findings**—Results of venous blood gas analysis were available for 8 of the 18 foals; initial venous blood pH data were available for 9 of the 18 foals. At the initial evaluation, blood pH values ranged from 7.0 to 7.4 (mean, 7.27 ± 0.12; median, 7.32; reference range, 7.36 to 7.4). Values of PaO2 ranged from 139 to 1,050 U/L (mean, 27 mEq/L; reference range, 25 to 33 mEq/L). Values of PaCO2 ranged from 18.2 to 45.5 mm Hg (mean, 28.4 ± 3.5 mm Hg; median, 33.9 mm Hg; reference range, 39 to 47 mm Hg). Initial venous bicarbonate concentrations ranged from 14.6 to 33.8 mEq/L (mean, 26.3 ± 6.0 mEq/L; median, 27 mEq/L; reference range, 25 to 33 mEq/L). Blood lactate concentration was measured in 5 of the 18 foals at initial evaluation; values were high in all 5 foals, ranging from 2.2 to 13.12 mmol/L (mean, 7.66 ± 4.26 mmol/L; median, 8.22 mmol/L; reference range, 0 to 2 mmol/L).

**NI diagnosis**—Nine of the 18 foals were assessed via a direct antiglobulin test (Coombs’ test); results of
the tests were positive in 8 of the 9 foals. Sera from 12 of the 18 dams were tested for anti-erythrocyte antibody. Anti-erythrocyte antibody was detected in sera obtained from 10 of the 12 dams; in 1 of the 2 dams with no detectable serum anti-erythrocyte antibody, anti-erythrocyte antibody was identified in colostrum. Three dam-foal pairs were assessed via the direct antiglobulin test (foal) and the serum anti-erythrocyte antibody test (dam). One of the 3 foals had negative results via the direct antiglobulin test, but the dam’s serum was positive for anti-erythrocyte antibody. The other 2 foals had positive results via the direct antiglobulin test, and their dams were positive for anti-erythrocyte antibody. The mule foal had positive results via the direct antiglobulin test, but the anti-erythrocyte testing of the dam’s serum was not performed.

Among the 10 foals in which the NI-associated antigen was indirectly identified via testing of their dams for anti-erythrocyte alloantibody, 4 were positive for Aa; 1 was positive for Qa; 2 were positive for Pa; 1 was positive for Qb, 1 was positive for Dg; and 1 was positive for Qa, Qb, and Qc. In the foal that was positive for Qa, Qb, and Qc, the strongest reaction was associated with Qb, but all 3 antigens were considered important. The antigen was not identified for 2 foals; donkey factor was assumed to be the NI-associated antigen in the mule foal (Table 1). Four of the 6 foals with the lowest initial Hct values (ie, the foals with Hct ≤11%) had anti-erythrocyte alloantibodies against the following blood factors identified in the mare’s serum or colostrum: Dg (n = 1), Aa (1), Qa (1), and the combination of Qa, Qb, and Qc (1).

Treatments—Polymerized bovine hemoglobin solution was administered to 2 of the 18 foals as initial treatment while each dam’s erythrocytes were washed in preparation for blood transfusions. The mule foal received 250 mL (5 mL/kg [2.23 mL/lb]) and a Thoroughbred foal received 1,250 mL (25 mL/kg [11.36 mL/lb]) of polymerized bovine hemoglobin solution. Administration of oxygen supplementation via nasal insufflation was recorded for 6 of the 18 foals.

Whole blood transfusions were administered to 10 of the 18 foals; 6 foals received 1 transfusion, 1 foal received 2 transfusions, and 2 foals (including the mule foal) received 3 transfusions. Number and volume of blood transfusions were unknown for 1 foal. Of the 9 foals for which the volume of blood administered during the first transfusion was recorded, the volume ranged from 750 to 4,000 mL (mean, 2,333 ± 887 mL; median, 2,200 mL). This volume range was estimated on a body weight basis to be 17 to 60 mL/kg (7.7 to 27.3 mL/lb; mean, 41 ± 12 mL/kg [18.6 ± 5.45 mL/lb]; median, 40 mL/kg [18.2 mL/lb]). Time to complete the transfusions ranged from 2 to 11 hours (mean, 5 ± 3 hours; median, 3 hours). Of these first whole blood transfusions, 5 were comprised of the dam’s washed RBCs, 1 was a combination of unwashed and washed mare’s RBCs, and 1 was whole blood from a crossmatched blood donor; the blood transfusion type was not recorded for 3 transfusions. Information regarding the resuspensions of the washed RBCs and the resulting PCVs of the transfusion preparations was not available from the medical records. The mule foal received 1 transfusion (750 mL [17 mL/kg]) of washed RBCs from the jenny followed by 2 smaller transfusions of washed RBCs from that dam (250 mL each [5.7 mL/kg [2.99 mL/lb]]. The mule foal also received a platelet-rich plasma transfusion from a crossmatched blood donor after the first washed RBC transfusion because of severe thrombocytopenia and on-going hemorrhage. Only plasma transfusions were administered to 6 of the 18 foals. The volume of the plasma transfusions ranged from 900 to 2,000 mL (mean, 1,142 ± 172 mL; medi-

---

**Table 1**—Data obtained from medical records of 18 foals with neonatal isoerythrolysis (NI) regarding breed, results of direct antiglobulin tests (Coombs’ tests) if performed, and identification of serum or colostrum anti-erythrocyte antibody in dams if performed.

NA = Not applicable.
Eight of 18 foals received 1 treatment with a corticosteroid (mean dosage, 0.19 mg/kg [0.09 mg/lb], IV). Five of these 8 foals received the cortico-steroid treatment before the first transfusion, and 7 of the 8 foals received the treatment on the day of initial evaluation. The mule foal received treatment with a corticosteroid (0.11 mg/kg [0.05 mg/lb], IV) between the treatment with the polymerized bovine hemoglobin solution and the transfusion of washed RBCs. One of the 8 foals that received corticosteroid treatment did not survive, and 2 of the 10 foals that did not receive corticosteroid treatment did not survive.

Heart and respiratory rates; rectal temperature; and hematologic, biochemical, and blood gas findings—For the following variables, no significant difference was detected between the values before and after the first blood transfusion: heart rate; respiratory rate; rectal temperature (within 4 and at 24 hours after the transfusion); RBC count; icterus index; plasma protein concentration; venous blood pH; venous base excess; anion gap; venous bicarbonate concentration; and serum creatinine, direct bilirubin, indirect bilirubin, total bilirubin, BUN, total CO2, and total protein concentrations. By use of a nonparametric Wilcoxon matched-pairs signed rank test, a significant (P = 0.047) difference in hemoglobin concentration between values before and after the first blood transfusion was detected in 7 foals. Before the transfusion, mean hemoglobin concentration was 4.5 ± 0.7 g/dL, and after the transfusion, the value was 8.0 ± 3.2 g/dL. By use of a nonparametric Wilcoxon matched-pairs signed rank test, a significant (P = 0.047) difference in Hct between values before and after the first blood transfusion was also detected in 7 foals. Before the transfusion, mean Hct was 11.8 ± 2.2%, and after the transfusion, the value was 21.6 ± 9.5%. Compared with findings before the first blood transfusion, there was a large increase in PcvO2 after the transfusion; before the transfusion, PcvO2 was 21.7 ± 44.5 mmHg, and after the transfusion, the value was 34.2 ± 37.4 mmHg. However, this finding was based on samples from only 2 foals and therefore must be interpreted with caution. For the following variables, no significant difference was detected between the values before and after the first plasma transfusion: heart rate; respiratory rate; rectal temperature (at 4 or 24 hours after the transfusion); hemoglobin concentration; Hct; RBC count; icterus index; venous blood pH; venous base excess; venous bicarbonate concentration; PcvO2; anion gap; and serum creatinine, direct bilirubin, indirect bilirubin, total bilirubin, BUN, total CO2, and total protein concentrations. When data regarding heart rate, rectal temperature, and respiratory rate for the 2 transfusion groups (plasma and blood) were combined for analyses within 4 and at 24 hours after transfusion, significant differences between values before and after transfusion were still not detected.

Outcome—Two foals were evaluated by veterinarians on field service only. Fifteen of the 18 foals survived to discharge (13 hospitalized foals with a mean time to discharge of 6 ± 5 days); 3 foals were euthanized as a result of a combination of sepsis, hepatic disease, or neurologic disease while hospitalized. Bacterial or fungal culture of blood from all 3 foals yielded positive results. In 1 foal, hemolysis of erythrocytes continued after a third blood transfusion. The specificity of the anti-erythrocyte antibodies was never identified in the serum of this foal’s dam. Results of the necropsy of this foal indicated chronic hemolysis, diffuse pigmented hepatopathy with multifocal hepatocellular necrosis, acute bile stasis, pigmentary nephrosis, and severe hemosiderosis of the spleen. Necropsy of the second foal that was euthanized revealed chronic cholangitis, biliary obstruction, bile stasis, giant cell hepatopathy, and hepatocyte syncytia formation; there was bone marrow hypoplasia, degenerative changes of the spleen, thymic atrophy, and Alzheimer type II gliosis of the frontal and parietal lobes of the brain. A necropsy of the third euthanized foal was not performed at the owner’s request. The 2 euthanized foals for which necropsies were performed had also undergone liver biopsy procedures. Among the 3 euthanized foals, 2 had initial Hct ≤ 11% and all 3 had initial Hct ≤ 15%. One of the 3 foals that was euthanized had high serum SDH (300 U/L), alkaline phosphatase (4,379 U/L), and aspartate aminotransferase (998 U/L) activities and high serum total bilirubin concentration. All 3 foals that were euthanized had high serum SDH activity and high serum total bilirubin concentration. The only anti-erythrocyte alloantibody identified in the dam’s serum of the 3 foals that were euthanized was Dg. Long-term follow-up data were available for 5 foals. One foal was euthanized within the first year of life for reasons unrelated to NI (ie, physisis, Salmonella group B enteritis, and a patent urachus). Via telephone conversations with the owners (a minimum of 1 year after discharge following the initial evaluations), the other 4 foals were reported to be alive, 1 of which was the mule foal. Because many of the foals had been hospitalized several years prior to commencement of this study, many of the owners could not be contacted because of change of ownership of the foal and lack of current contact information.

Comparison of survival-to-discharge rates with treatments revealed that 8 of 10 foals that received whole blood transfusions survived to be discharged from the hospital. Five of 6 foals that received only a plasma transfusion survived to discharge, and 2 of 2 foals that received no transfusions survived to discharge. The whole blood transfusions were then divided by type. Five of 5 foals that received washed RBCs from their respective dams survived to discharge. The 1 foal that received a combination of unwashed and washed RBCs from its dam was euthanized. The foal that received a crossmatched blood transfusion and 2 of 3 foals that received a whole blood transfusion of unknown type survived to discharge.

Discussion

To the authors’ knowledge, there are no reports of immune-mediated hemolytic anemia in neonatal foals without a prior history of incompatible blood or plasma transfusions.1 A positive result of a direct antiglob-
In the present study, there was a slight overrepresentation of fillies among the foals with NI relative to the hospital's neonatal equid population. This finding may reflect the small number of foals in our study or the relative frequencies of erythrocyte antigens in the horse population served by the VMTH.

It has been previously reported that foals with NI develop clinical signs within 5 days of birth. Our data suggest that this interval may be as long as 12 days (median time to development of signs after birth, 2.5 days). This extended age range for development of clinical signs of NI could represent subclinical or mild NI in foals that subsequently became clinically apparent. For example, the 12-day-old foal in the study of this report was evaluated as a field service case; signs of NI were mild, and the foal did not require hospitalization but did receive a blood transfusion. If the hemolytic process was slow or mild, foals could have compensated for the low Hct and RBC mass. Iatrogenic immune-mediated hemolytic crises, as might develop after administration of incompatible blood transfusions, were ruled out in the foals of the present study on the basis of anamnesis; none of the foals in our study had previously received plasma or blood product transfusions, and in most instances, hemolysin or agglutinin alloantibody was detected in the mares’ sera.

Tachypnea and icterus were the most notable abnormal physical examination findings among the foals with NI. Anemia or low oxygen content would likely stimulate the respiratory center response, resulting in tachypnea. Reduced mentation was also common. All 3 foals that were described as obtunded at the initial evaluation were discharged from the hospital alive, but 1 was later euthanatized as a result of sepsis and salmonellosis.

Hematologic findings at the initial evaluation were consistent those of previous reports of NI in foals, which included various degrees of anemia associated with clinical disease. At the initial evaluation, hemoglobin concentration can falsely increase Hct. In the present study, 2 foals had Hct within the reference range and 2 foals had Hct close to the reference range at the initial evaluation; following rehydration with plasma transfusions or administration of crystalloids, these foals became anemic. Interestingly, the former 2 foals both had failure of passive transfer, which may have resulted in poor absorption of the alloantigen from colostrum. The severity of the hemolytic crisis (determined by the antigenicity of the alloantigen) can also affect the rate at which Hct decreases. Some foals had WBC counts near the upper reference limit with high band neutrophil concentrations. Similar findings are associated with systemic inflammatory response syndromes (SIRS), such as sepsis. Neutrophilia develops as a result of sympathoadrenal and neurohormonal responses to anemia. Thrombocytopenia has been identified concurrently with NI, most commonly in mule foals. In our study, 3 of 18 foals had concurrent thrombocytopenia and anemia, which highlights the fact that thrombocytopenia may be present in some foals in NI. Whether this abnormality is a result of alloimmune thrombocytopenia, coagulopathies, or other causes is unknown and requires further investigation. All 3 foals were confirmed to be thrombocytopenic via platelet counts performed by an automated analyzer on blood samples collected in tubes contain-
ing sodium citrate. Platelet-associated alloantibody testing was performed on a whole blood sample from the mule foal, but results were negative. Examination of the bone marrow of this foal was consistent with a thrombolytic process via maternal antibodies. The reliability of platelet-associated alloantibody testing for alloimmune thrombocytopenia in horses and mules has been questioned. Coagulopathies with activation or consumption of platelets as a result of SIRS or hypoxic-ischemic injury may also explain the thrombocytopenia detected in these NI-affected foals. The thrombocytopenia (48,000 platelets/µL) in 1 foal could have developed secondary to disseminated intravascular coagulation associated with sepsis. The mule foal required treatment with platelet-rich plasma from a VMTH donor horse because of active hemorrhage. The other 2 foals with thrombocytopenia responded to whole blood transfusions, and all 3 were discharged from the hospital alive.

At the initial evaluations of the NI-affected foals, serum and plasma biochemical variables were consistent with previously reported values except for the additional abnormality of high serum direct bilirubin concentration. To our knowledge, direct hyperbilirubinemia in association with NI has never been described in the peer-reviewed literature and likely reflects hepatic disease in our population of foals. Hepatocellular damage leading to direct hyperbilirubinemia is suspected to develop secondary to excessive bilirubin accumulation in hepatocytes and iron toxicosis as a result of massive hemosiderosis as well as anemic hypoxia. Serum SDH activity correlated with these findings. Urine abnormalities were consistent with hyperbilirubinemia and hemolytic disease.

Neonatal isoerythrylosis has historically been associated with adequate passive transfer of IgG because a foal absorbs the dam's colostrum that contains the anti-erythrocyte antibodies. Interestingly, 4 of 15 foals in our study had failure of passive transfer (defined as whole blood immunoglobulin concentration < 400 mg/dL). Three of these 4 foals did not require blood transfusions, possibly indicating more mild disease associated with poor passive transfer of colostral antibodies. One of these 4 foals with failure of passive transfer did not survive to discharge because of sepsis-associated complications. There are several theories regarding development of NI in the face of failure of passive transfer. It is possible that the anti-erythrocyte antibodies may have different antigenic reactivities or sensitivities because certain blood groups are more antigenic than others; to cause erythrocyte destruction, lower concentrations of some antibodies may be required, compared with concentrations of other anti-erythrocyte antibodies. Other theories include consumption of IgG secondary to concurrent sepsis (sepsis was identified in 3 of the 4 foals with failure of passive transfer) or antibody binding to RBCs that prevents measurement of free IgG in whole blood via the immunoassay.

At initial evaluation of the NI-affected foals, results of venous blood gas analyses were consistent with metabolic acidemia and high anion gap metabolic acidosis. Anemia causes peripheral tissue hypoxia and increased lactic acid production; in the foals of our study, low PcvO2 and high blood lactate concentrations were evidence of this. Oxygen extraction increases in tissues with low oxygen delivery, resulting in levels of PcvO2 that are below the lower reference limit. Unfortunately, results of arterial blood gas analyses were unavailable to estimate oxygen extraction ratios. As indicated by the oxyhemoglobin dissociation curve, a decrease in blood pH shifts the curve to the right, and unloading of oxygen from hemoglobin to the peripheral tissues is facilitated. High blood lactate concentrations are also consistent with increased production of lactate as a result of inadequate peripheral oxygen delivery, although increased production due to catecholamine or inflammatory mediators may have also contributed to the hyperlactatemia. Compared with initial values, significant differences in hemoglobin concentration and Hct were detected after the administration of whole blood transfusions, suggesting an increase in oxygen-carrying capacity provided by the transfusions. In 2 foals in which PcvO2 was measured before and after the first blood transfusion, there was a large posttransfusion increase in that value, reflecting improved peripheral tissue oxygenation. The use of PcvO2 as a transfusion trigger in foals with NI warrants further study. Based on the results of the present study, it appears that not all foals with clinical signs of NI need to be treated with whole blood transfusions. Affected foals with high Hct values, slower rates of RBC hemolysis, more normalized clinical variables such as heart and respiratory rates and mentation, and mild abnormalities in PcvO2 may require only supportive care including colloidal administration via plasma transfusions. Foals with hypoproteinemia may be best treated with colloids to avoid further dilutional decreases in serum total protein concentration by the crystalloids. Evidence also suggests that many cases of NI are subclinical.

It would be expected that the clinical variables (heart rate, temperature, and respiratory rate) measured in the NI-affected foals within 4 hours of completion of plasma and blood transfusions would be decreased, compared with initial values, because of an increase in the oxygen-carrying capacity of the blood. In the present study, there were no significant differences in those clinical variables between values before and after transfusions. Following both types of transfusion, respiratory rate and rectal temperature actually increased, which could be explained by concurrent SIRS or mild transfusion reactions. At 24 hours after transfusions, reevaluation of all clinical variables still revealed no significant differences, compared with values before transfusions. Because clinical data before and after the first transfusion were available for only 3 foals that were administered plasma and 5 foals that were administered blood, the sample was too small to detect significant differences. The clinical data for the 2 transfusion groups were then combined (plasma and blood) for analyses at 4 and 24 hours after transfusion, but significant differences between values before and after transfusion were still not detected.

The present retrospective study included too few foals to examine risk factors for death associated with
NI. However, microbial culture of blood yielded positive results for all 3 foals that were euthanatized. At the initial evaluation, Hct values were lower in the 3 foals that were euthanatized than values in the foals that were not euthanatized, but the difference was not significant, which may be a consequence of the low number of foals that were euthanatized. Of all foals in the study, the foals with Hct values <11% did have significantly higher serum SDH activities, compared with the foals with Hct values ≥11%, and both foals in which liver biopsies were performed were euthanatized, which may suggest that another possible risk factor associated with outcome of NI-affected foals could include the degree of concurrent liver disease. Two of 3 nonsurviving foals had high serum liver enzyme activities, which may also reflect an association between liver disease and outcome. However, because there were so few nonsurviving foals in our study, it is difficult to draw strong conclusions. The number of transfusions required to stabilize the foal and the particular anti-erythrocyte antibody may also be possible risk factors associated with outcome of NI-affected foals.

In the study of this report, the alloantigen Dg and the combination of Qa, Qb, and Qc antigens were associated with the development of NI in foals. Our data indicated that NI-affected foals may have concurrent liver disease as a result of low oxygen content in blood associated with anemia. Blood transfusions administered to affected foals can improve tissue oxygenation, as evidenced by increases in hemoglobin concentration, Hct, and $P_{O_2}$. Although blood transfusions are not necessary for every foal with NI, treatment or support of tissue oxygenation by means of crystalloid, colloid, or blood transfusion therapy can result in a favorable prognosis, as indicated by survival of NI-affected foals that had not received blood transfusions.
